## **Abstract**

Polymer architecture plays critical roles in both bulk rheological properties and microscale macromolecular dynamics in entangled polymer solutions and composites. Ring polymers, in particular, have been the topic of much debate due to the inability of the celebrated reptation model to capture their observed dynamics. Macrorheology and differential dynamic microscopy (DDM) are powerful methods to determine entangled polymer dynamics across scales, yet they typically require different samples under different conditions, preventing direct coupling of bulk rheological properties to the underlying macromolecular dynamics. Here, we perform macrorheology on composites of highly-overlapping DNA and dextran polymers, focusing on the role of DNA topology (rings versus linear chains) as well as the relative volume fractions of DNA and dextran. On the same samples under the same conditions, we perform DDM and single-molecule tracking on embedded fluorescent-labeled DNA molecules immediately before and after bulk measurements. We show DNA-dextran composites exhibit unexpected non-monotonic dependences of bulk viscoelasticity and molecular-level transport properties on the fraction of DNA comprising the composites, with characteristics that are strongly dependent on the DNA topology. We rationalize our results as arising from stretching and bundling of linear DNA versus compaction, swelling, and threading of rings driven by dextran-mediated depletion interactions.

## **1. Introduction**

Ring polymers have been the topic of fervent investigation for decades due to their intriguing rheological and dynamical properties, biological significance, and industrial applications. For example, DNA naturally occurs in ring formation, and conversion between supercoiled and open circular (ring) topology plays a critical role in DNA replication and repair [1-3]. Further, ring polymers can tune the rheological properties of polymeric blends for commercial and industrial use [4-6]. While the dynamics of entangled linear polymers are well described by the reptation model developed by de Gennes and Doi and Edwards [7, 8], its extension to ring polymers is not straightforward due to their lack of free ends [9-11]. The extent to which ring polymers form entanglements and corresponding entanglement plateaus, the effect and persistence of threading of one polymer by another, and the relaxation modes available to ring polymers remain topics of debate [12-17].

Previous rheological studies have shown that entangled ring polymers do not display the same entanglement plateaus that their linear counterparts do [12, 13, 18-20], indicating a different rheological signature of the topological constraints in rings, generally referred to as entanglements. Entangled rings are predicted to adopt double-folded or amoeba-like branched structures that undergo modified reptation that is faster than their linear counterparts [9, 21-24]. At the same time, studies have shown that rings undergo very slow relaxation compared to entangled linear chains, such that the final scaling of the storage and loss moduli in the terminal flow regime,  $G'(\omega) \sim \omega^2$  and  $G''(\omega) \sim \omega^1$ , is not reached [12, 17, 25-28].

Simulations of concentrated ring polymer solutions have shown evidence of ring-ring threadings [29] that, for sufficiently overlapping large rings, manifest as glassy dynamics with kinetically arrested states and heterogeneous transport [30, 31]. Within this framework, the rings adopt crumpled lattice-animal conformations with sufficient swelling and self-avoidance to allow for ring-ring threadings. Conversely, rings in dense solutions and melts have also been predicted to adopt collapsed double-folded structures, which are much less likely to become threaded [21, 32, 33]. Finally, simulations have shown that most rings are threaded by multiple rings with a wide range of threading lifetimes, for entanglement densities as low as  $Z \approx 10$  entanglements per chain, prolonging their relaxation timescales and enhancing the dynamic heterogeneity [21, 34, 35].

In addition to ring-ring threading events, threading of rings by a small percentage of linear polymer ‘contaminants’ that nearly all synthesis techniques produce, likely also contribute to the reported slow relaxation of nominally ‘pure’ entangled rings [36]. Linear DNA contaminants are also hard to avoid during purification and preparation of concentrated solutions of large ring DNA molecules, which have been studied extensively to elucidate the role of polymer topology on the dynamics of entangled polymer solutions [15, 37-42]. Moreover, simulations have shown that the relaxation timescale of a threaded ring is significantly increased when threaded by multiple chains (rings or linear) versus a single chain; and that threading by linear chains is typically longer-lived than ring threading events [21, 34]. The dominant relaxation mode of a ring with long-lived or multiple threadings is constraint release, whereby a polymer relaxes stress by the threading polymer unthreading itself and releasing its constraint [14, 26, 36], rather than the faster mode of reptation that otherwise dominates entangled polymer systems [8, 23]. These diverse relaxation timescales associated with different topologies, sizes and numbers of threading polymers, give rise to heterogeneous dynamics in entangled ‘pure’ rings and ring-linear blends [35, 43, 44], similar to those reported in simulations of entangled ring polymer solutions [30, 31, 45]. While the inclusion of linear chain threading is often needed to recapitulate stress relaxation in nominally ‘pure’ ring melts, long-lived ring-ring threadings, along with multiple ring threading events, slow the dynamics considerably and are also predicted to contribute significantly to the slow relaxation of entangled rings [21, 30, 34].

The different rheological properties of entangled rings and linear polymers also manifests in the frequency dependence of the shear viscosity  $\eta(\omega) \sim \omega^{-\nu}$ , an indicator of entanglements and how well polymers are able to align with shear flow. Highly entangled flexible linear polymer melts

exhibit thinning  $\eta(\omega) \sim \omega^{-\gamma}$  with  $\gamma \approx 0.9-1$  [8, 20], whereas entangled linear DNA solutions in good solvent conditions exhibit slightly reduced thinning with  $\gamma \approx 0.6 - 0.9$  [16, 46, 47]. Entangled ring melts and solutions have been reported to exhibit weaker thinning than their linear counterparts ( $\gamma \approx 0.4 - 0.6$ ) owing to their reduced ability to conformationally align with shear flow [16, 20].

In ring-linear blends, threading of rings by linear chains have been shown to have profound effects on the rheology and dynamics [12, 25, 26, 36, 48-50], including emergent entanglement plateaus, increased zero-shear viscosity and thinning, suppressed relaxation, and hindered diffusion as compared to monodisperse systems of linear chains or rings [16, 50-54]. For example, previous studies have shown that a small fraction of linear chains ( $>0.05$ ) can cause entangled ring melts to transition from power-law stress relaxation [25, 55] to exhibiting entanglement plateaus comparable to their linear counterparts [19]. At the same time, a small fraction of rings (up to  $\sim 0.3$ ) added to entangled linear polymer melts has been shown to increase the viscosity up to  $\sim 2$ -fold [14, 26]. Further, recent simulations have shown that rings in a melt of short linear polymers (up to  $\sim 10$ -fold shorter than the rings) exhibit more swollen conformations, due to excess chain-end free volume effects of the interpenetrating linear chains [54]. These swollen rings diffuse faster than in their own melt, demonstrating that any threading by the short linear chains is transient and actually enhances rather than restricts ring mobility. However, when the length of the surrounding linear chains exceeds the entanglement length, ring diffusion drops substantially owing to long-lived threadings by the entangled linear chains. Finally, the addition of linear chains to entangled rings increases the thinning exponent to be comparable to or larger than that for entangled linear polymers with reported values of  $\gamma \approx 0.7 - 0.9$  [16, 19], suggesting that threading of rings by linear chains aids in stretching and aligning rings along the flow direction.

While the role of polymer topology in entangled melts, solutions and blends continues to be widely investigated, how topology modulates the rheology and dynamics of composites of two distinct polymeric species with different sizes, stiffnesses and structures remains scarcely explored [56]. Free energy minimization of composites, typically comprising a polymer matrix and a ‘filler’ species, leads to emergent behavior, such as non-monotonic dependence of viscoelastic and transport properties on the relative fraction of each species [57-61]. Emergent phenomena in composites can arise from entropically-driven polymer bundling and flocculation [56, 60, 62], enhanced miscibility and solubility [56, 61, 63, 64], or even liquid-liquid phase separation [65, 66].

For example, we previously showed that composites of flexible DNA and  $\sim 200$ -fold stiffer actin filaments exhibit enhanced stiffening and suppressed relaxation compared to networks of DNA or actin alone due to small-scale actin bundling, driven by DNA, that stiffens and strengthens the composite [60]. This phenomenon arises from depletion interactions, ubiquitous in biology, in which macromolecules of one species (actin) are driven together to maximize the available volume (and thus entropy) of the other smaller, faster and/or more abundant species (DNA). The unexpected non-monotonic dependence of composite stiffening on the actin fraction is a result of

competition between actin bundling, which stiffens the actin network and suppresses thermal fluctuations, and actin network connectivity required to provide a percolated scaffold to support and entangle with the DNA. Similar non-monotonic emergence has been reported in crosslinked composites of cytoskeleton filaments [57, 61, 67]. The general phenomenon of depletion interactions driving opposing effects of increased polymer self-association and reduced polymer network connectivity, resulting in non-monotonic dependences of dynamics on the varying fractions of the polymers and depletants, appears to be a signature of a wide range of polymer composites [56, 60, 68].

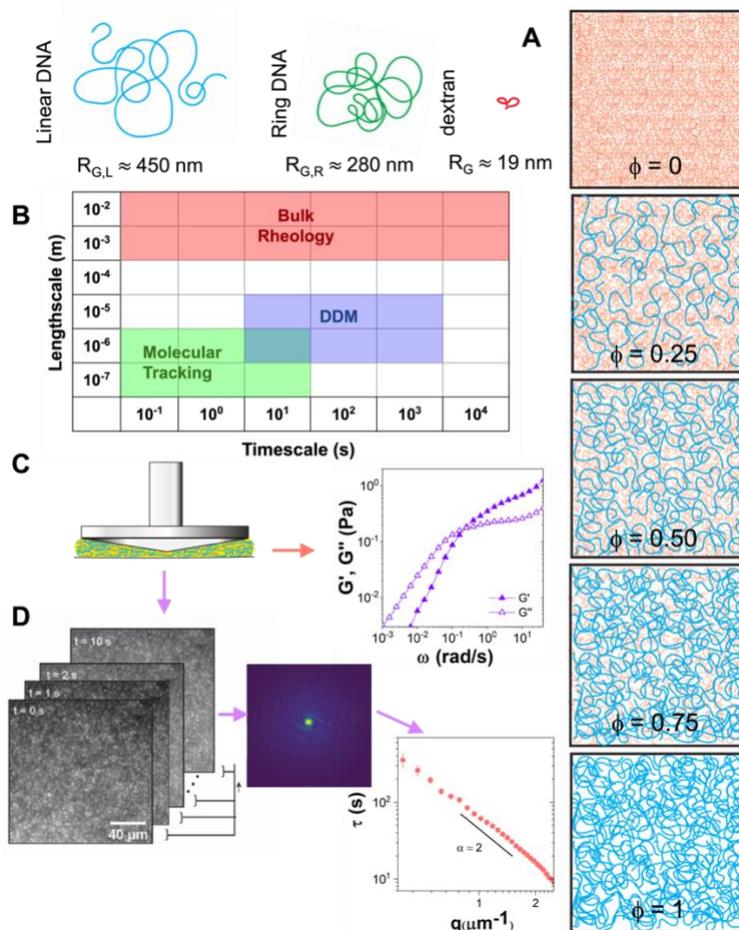

Similar emergent phenomena have also been shown to arise in composites of polymer and colloids [69-71] or nanoparticles [72], which have been investigated extensively to understand the role of depletion interactions in composites [73]. For example, a recent study investigating the role of short chains added to composites of long polymers and nanoparticles (NPs) reported a non-monotonic dependence of composite strength on the ratio of short, NP-adsorbing polymers and long linear polymers [72]. The peak in mechanical strength, which occurs at  $\sim 40\%$  short chains, is attributed to an optimal balance of stretching of the long chains and an associated increase in their overlap density with reduced polymer entanglements and connectivity as the number of long NP-bridging polymers is reduced. The competition between enhanced polymer self-association and network connectivity is similar in spirit to that reported in other composite systems [56, 60, 68].

Similar to Ref [72], we previously found stretching of tracer linear DNA from random coils to elongated snake-like conformations when crowded by small dextran polymers at sufficient dextran volume fraction ( $\sim 30\%$ ,  $11c^*$ ) [74]. Conversely, ring DNA condensed into more compact spherical conformations under the same conditions [75]. Both elongation and compaction are volume-minimizing conformations, driven by entropy maximization of the dextran crowdors (i.e., the depletion interaction). These studies also examined the diffusion of the tracer DNA crowded by dextran, reporting subdiffusive dynamics for linear DNA at short lag times ( $\Delta t < 10$  s) and normal diffusion for longer lag times ( $10$  s  $< \Delta t < 50$  s) [74]. Conversely, ring DNA exhibited normal diffusion across all lag times [75]. For  $\Delta t > 10$  s, the diffusion coefficients for both ring and linear DNA decreased with increasing dextran concentration, but with more modest scaling than classically expected owing to their volume-minimizing conformations.

The complex and intriguing effects of polymer end-closure on rheology and macromolecular dynamics [10, 18, 20, 76], combined with the rich emergent phenomena that polymer composites exhibit [58, 68, 77-79], motivated us to examine the molecular-level transport and bulk rheological properties of concentrated composite solutions of DNA and dextran (Fig 1). We fix the polymer overlap in all cases and investigate solutions of linear DNA and dextran with varying volume fractions of DNA  $\phi$ . We compare our results for each  $\phi$  with those of a more complex composite system in which we replace 90% of the linear DNA with ring DNA (keeping 10% linear) while maintaining  $\phi$ .

Our work elucidates the dynamics of these complex DNA-dextran composite solutions from the scale of single polymers ( $\sim 10^2$  nm) to that of the macroscopic bulk ( $\sim$ cm). Specifically, we couple

macrorheology with fluorescence microscopy, differential dynamic microscopy (DDM) and single-molecule tracking to directly connect the bulk rheological properties of the composite solutions to the microscale transport properties of the comprising DNA.

**Fig 1. Experimental platform to investigate bulk rheology and molecular-level dynamics in composites of DNA and dextran.** (A) Cartoon of macromolecules that comprise the composites, with their corresponding radius of gyration  $R_G$  listed: 25-kbp linear DNA (blue), 25-kbp ring DNA (green) and 500 kDa dextran (red). The panel on the right depicts  $11c^*$  composites of linear DNA and dextran at all DNA volume fractions  $\phi$  that we investigate:  $\phi = 0$  (100% dextran),  $\phi = 0.25$  (25% DNA, 75% dextran),  $\phi = 0.50$  (50% DNA, 50% dextran),  $\phi = 0.75$  (75% DNA, 25% dextran), and  $\phi = 1$  (100% DNA). (B) Lengthscales and timescales probed by the different techniques we use: bulk rheology, differential dynamic microscopy (DDM), and molecular-tracking. (C) We use a DHR3 rheometer to measure bulk viscoelastic properties of composites, including the elastic and viscous moduli  $G'(\omega)$  (filled symbols) and  $G''(\omega)$  (open symbols). (D) Immediately before and after bulk rheology measurements, we capture time-series of labeled DNA molecules diffusing in the sample using the fluorescence microscopy capabilities of the rheometer. We perform DDM analysis on captured time-series to determine the image structure function  $D(q, \Delta t)$  as a function of lag time,  $\Delta t$ , and wavevector,  $q$ . By fitting  $D(q, \Delta t)$ , we determine the density fluctuation decay times  $\tau$  as a function of  $q$  to describe the DNA dynamics. Data shown in (C) and (D) is for linear DNA at  $\phi = 1$ .

While both macro- and micro-rheological techniques have been extensively used to investigate entangled polymers and other soft materials, these distinct measurements are typically performed on different samples with different preparation methods, chamber geometries, and sample volumes [80, 81]. As such, direct connection between the properties at these two scales is non-trivial [47, 82-84]. We overcome these limitations by performing imaging and rheology measurements in the same sample using a rheometer with high-speed fluorescence imaging capabilities. Further, we track DNA molecules comprising the composites, rather than embedded probes (as is typically done in microrheology experiments [85]), to directly report macromolecular dynamics via DDM.

Our results reveal a surprising non-monotonic dependence of the rheological properties on the fraction of DNA comprising the composites, with 75%-25% DNA-dextran composites exhibiting uniquely suppressed dissipation coupled with prolonged relaxation times and subdiffusion. We argue that this emergent behavior, that is strongly dependent on DNA topology, arises from entropically-driven self-association and stretching of linear DNA versus swelling and threading of ring DNA.

## 2. Materials and Methods

**2.1 DNA:** We prepare solutions of double-stranded DNA, 25 kbp in length, *via* replication of fosmid constructs in *Escherichia coli* followed by extraction, purification and concentrating as described previously [86-88]. Briefly, to replicate DNA, *E. coli* cultures containing the fosmid clone is grown from frozen glycerol stocks. To extract the DNA, cells are lysed via treatment with an alkaline solution. The extracted DNA is then renatured via treatment with an acidic detergent, precipitated in isopropanol, washed with 70% ethanol, and resuspended in TE10 buffer (10 mM Tris-HCl (pH 8), 1 mM EDTA, 10 mM NaCl). To purify the DNA, the solution is treated with Rnase A (to remove contaminating RNA) followed by phenol-chloroform extraction and dialysis (to remove proteins). We assess purity using UV absorbance and gel electrophoresis [87]. The purified DNA solution has a 260/280 absorbance ratio of  $\sim 1.8$ , in the accepted range for pure DNA with minimal protein contaminants [89], and no detectable RNA (which manifests as a low MW smear on a gel) (Fig S1).

We use gel electrophoresis to determine a concentration of 3.25 mg/mL of our purified solution, consisting of  $\sim 90\%$  relaxed circular (ring) and  $\sim 10\%$  linear DNA (Fig S1). Gel analysis is performed using Life Technologies E-Gel Imager and Gel Quant Express software (Fig S1). We convert half of the purified stock DNA solution to linear topology via treatment with the restriction enzyme *ApaI* (New England Biolabs). We confirm complete conversion to linear topology via gel electrophoresis (Fig S1).

The radii of gyration for the ring and linear DNA are  $R_{G,R} \simeq 280$  nm and  $R_{G,L} \simeq 450$  nm, respectively [88]. We compute polymer overlap concentrations for the linear and 90% ring DNA solutions via  $c^* = (3/4\pi)(M/N_A)/(f_L R_{G,L}^3 + (1 - f_L) R_{G,R}^3)$  where  $M$  is the molecular weight and  $f_L$  is the fraction of linear DNA in the sample ( $f_L = 1$  and  $0.1$  for linear and ring solutions,

respectively) [8, 90], resulting in  $c_{90R}^* \approx 220 \mu\text{g/mL}$  and  $c_L^* \approx 71 \mu\text{g/mL}$  for ring and linear DNA, respectively. We note that our  $c^*$  calculations assume random coil configurations of similar size to the dilute condition, and do not account for any swelling or compaction that may arise in the entangled and crowded systems studied here. To image DNA for DDM and particle-tracking, we fluorescent-label a fraction of the DNA molecules with MFP488 (Mirus) using the manufacturer-supplied *Label IT* Labeling Kit and corresponding protocols (Mirus). The excitation/emission spectrum for MFP488 is 501/523 nm and the dye molecule to DNA base pair ratio is 5:1.

**2.2 Dextran:** We use molecular biology grade dextran (Fisher BioReagents BP1580100, Lot #196289), with molecular weight 500 kDa and  $R_G \approx 19 \text{ nm}$  [91]. The manufacturer-provided certificate of analysis shows suitability for protein fractionation and gel permeation chromatography, with heavy metal impurities and ignition residues below industry standards for molecular biology grade purity. To prepare composites, dextran is dissolved in TE10 buffer at a concentration of 28.9 mg/ml ( $11c^*$ ) and homogenized via slow rotation at room temperature for >24 hrs. In the present study, as well as our previous studies investigating the diffusion of tracer DNA in crowded dextran solutions [74], we see no signs of adsorption or other non-steric interactions between dextran and DNA.

**2.3 Sample Preparation:** We prepare each sample at a volume of 350  $\mu\text{L}$  comprising different volume fractions of DNA and dextran solutions each at  $11c^*$ , corresponding to 2.42, 0.78 and 28.9 mg/ml for ring DNA, linear DNA and dextran, respectively. We add 2  $\mu\text{L}$  of labeled ring or linear DNA tracers to each sample for microscopy measurements. Each sample is prepared at least 4 days prior to experiments and rotated at  $4^\circ\text{C}$  to mix and equilibrate. An oxygen scavenging system (45  $\mu\text{g/mL}$  glucose, 43  $\mu\text{g/mL}$  glucose oxidase, 7  $\mu\text{g/mL}$  catalase, 5  $\mu\text{g/mL}$   $\beta$ -mercaptoethanol) is added to inhibit photobleaching. Composites comprising both DNA and dextran are prepared by mixing varying volume fractions of  $11c^*$  DNA and dextran solutions, which we quantify by the volume fraction of the DNA solution  $\phi$ . We investigate samples with  $\phi = 0$  (0% DNA, 100% dextran)  $\phi = 0.25$  (25% DNA, 75% dextran),  $\phi = 0.5$  (50% DNA, 50% dextran),  $\phi = 0.75$  (75% DNA, 25% dextran), and  $\phi = 1$  (100% DNA, 0% dextran). For each  $\phi$ , we prepare samples using either the linear DNA solution or the 90-10 ring-linear DNA solution (which we refer to as ‘90-ring’ throughout the paper).

**2.4 Rheometry:** We use a Discovery Hybrid Rheometer 3 (DHR3, TA Instruments) with a  $1^\circ$  steel cone geometry to perform bulk rheology measurements. We use a glass slide as the bottom plate to enable imaging of fluorescent-labeled DNA in the samples. To prevent evaporation during the experimental cycle we apply mineral oil around the geometry and the sample. To measure linear viscoelastic moduli,  $G'(\omega)$  and  $G''(\omega)$ , we perform two identical frequency sweeps from  $\omega = 0.001$  to 100 rad/s at 5% strain (well within the linear regime as determined by amplitude sweeps). Each frequency sweep lasts  $\sim 6.5$  hours with individual frequency measurements spaced 30 mins apart. All data shown are above the measurable torque minimum of 0.5 nN·m for the DHR3 rheometer.

**2.5 Fluorescence Microscopy:** The DHR3 is outfitted with a Modular Microscope Accessory (TA Instruments) with a  $40\times$  0.6 NA objective (Nikon), blue-light LED source, 490/525 nm

excitation/emission filters, and a Hamamatsu ORCA-Flash 2.8 CMOS camera to enable imaging of MPF488-labeled DNA in the blends. Immediately before and after each bulk rheology measurement, we collect three 512×512 pixel videos of 2000 frames at 1 fps. We use 2×2 pixel binning to improve signal to noise, resulting in 256×256 images with an effective pixel size of 0.312 μm. This binning, along with the dense concentration of labeled DNA in each field-of-view (Fig S2), is optimized for statistically robust DDM measurements. However, it prohibits accurate measurement of changes to the conformational size and shape of individual DNA molecules. Sample frames from before and after videos are shown in Fig S2.

**2.6 Differential Dynamic Microscopy (DDM):** For DDM analysis (Fig 3), we split the videos into 256×256 pixel regions of interest (ROIs) which we analyze separately. We use custom-written scripts (Python) to perform DDM. For standard DDM analysis, one takes two-dimensional Fourier transforms of differences between images separated by a range of lag times  $\Delta t$  in order to quantify how the degree of correlation decays with lag time as a function of the wave vector  $q$ . Because this standard correlation function is sensitive to global drift of the sample, we use a slightly modified correlation function referred to as the far-field DDM (FF-DDM) function. Previous work has shown that by using FF-DDM, the DDM correlation function,  $D(q, \Delta t)$ , is less sensitive to drift [92, 93]. As with standard DDM analysis, we fit the far-field DDM matrix to  $D(q, \Delta t) = A(q)[1 - f(q, \Delta t)] + B(q)$ , where  $f(q, \Delta t)$  is the intermediate scattering function (ISF),  $A(q)$  is the amplitude, and  $B(q)$  is the background. To determine the type of motion and the corresponding rate, we model the ISF as a stretched exponential:  $f(q, \Delta t) = e^{-(\Delta t/\tau(q))^\gamma}$  where  $\tau(q)$  is the decay time and  $\gamma$  the stretching exponent. The use of a stretched exponential as opposed to a simple exponential has been shown to better fit dynamics in confined or entangled systems [94, 95]. Scaling of  $\tau(q) \sim q^{-2}$  is indicative of normal Brownian diffusion (i.e.,  $MSD \sim t$ ), whereas a decay time that depends less strongly on  $q$  has been associated with more arrested or confined motion [96, 97]. Error bars shown in Fig 3 are standard error across all ROIs and videos, representing sample-to-sample variation. Example ISFs and fits are shown in Fig S4 and sample-to-sample variation in the ISFs is shown in Fig S5. Estimates of diffusion coefficients  $D$  and their errors are based on the fits to  $\tau(q) = 1/Dq^2$  over the range of  $q$  from 0.39 μm<sup>-1</sup> to 2.44 μm<sup>-1</sup>. For some samples, particularly for  $\phi = 0.75$  composites, we observe a  $q$ -dependence that indicates nearly arrested rather than diffusive dynamics [97]. While we still compute an effective diffusion coefficient for these samples, because the dynamics differ from normal diffusive transport, we also fit each curve to  $\tau(q) = 1/Kq^\alpha$  where  $\alpha$  is a free parameter that is  $\sim 2$  for normal diffusion and approaches zero for halted or arrested dynamics.  $K$  is the generalized transport coefficient that is equivalent to  $D$  when  $\alpha = 2$ .

**2.7 Single-molecule tracking (SMT):** For single-molecule tracking experiments, we image the MFP488-labeled DNA using an Olympus IX73 inverted fluorescence microscope with a 60× 1.2 NA oil immersion objective (Olympus). We collect five 512×512 pixel videos of 2000 frames at 10 fps for each sample. We use custom particle-tracking scripts (Python) to track the center-of-mass of individual DNA molecules and measure their frame-to-frame  $x$  and  $y$  displacements

$(\Delta x, \Delta y)$  from which we compute the ensemble averaged mean-squared displacements ( $\langle \Delta x^2 \rangle$ ,  $\langle \Delta y^2 \rangle$ ). We fit the average of  $\langle \Delta x^2 \rangle$  and  $\langle \Delta y^2 \rangle$  (i.e.,  $MSD$ ) versus lag time  $\Delta t$  to a power-law function  $MSD \sim \Delta t^\beta$  where  $\beta$  is the subdiffusive scaling exponent. For a system exhibiting normal diffusion,  $\beta=1$ , while  $\beta < 1$  indicates anomalous subdiffusion. Error bars listed in Fig 4 are based on fits of the data to  $MSD \sim \Delta t^\beta$ .

### 3. Results and Discussion

#### 3.1 System Details

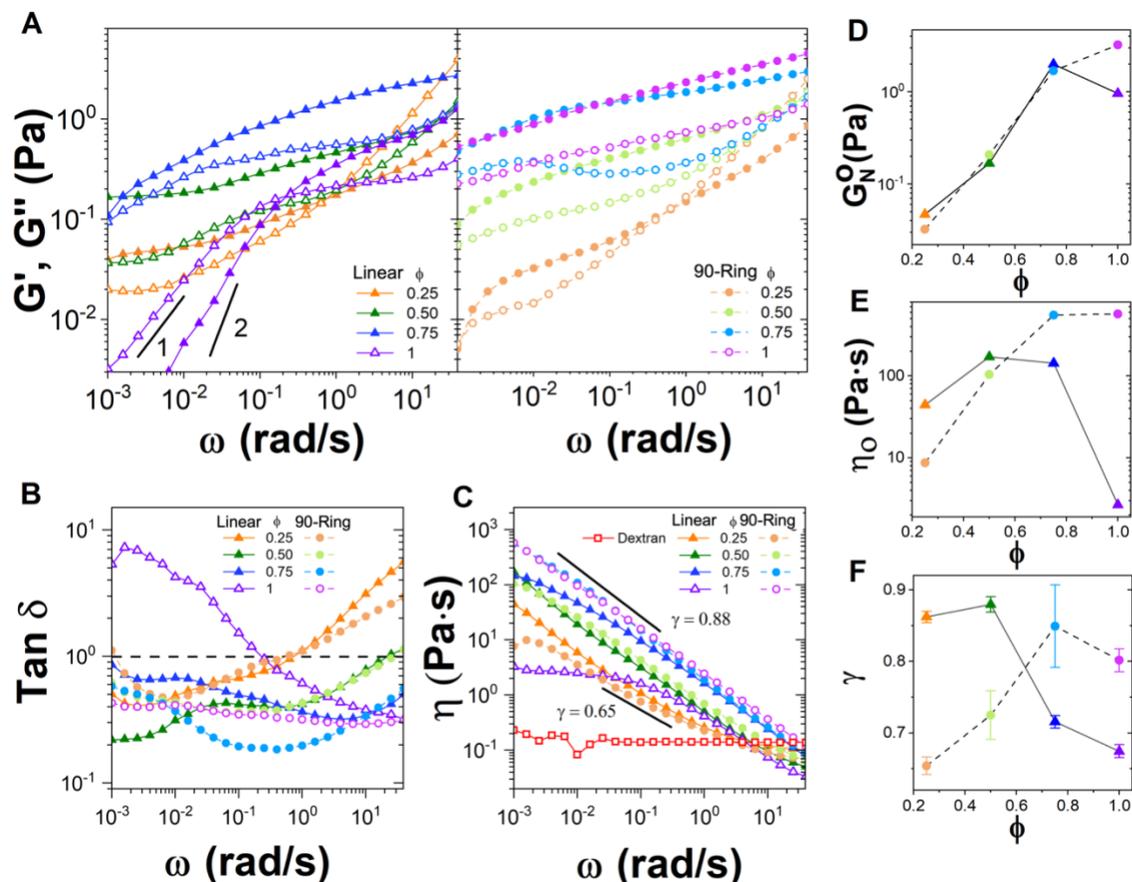

In all of our experiments described below, we fix the total polymer concentration to  $11c^*$  to ensure that the molecules are highly overlapping, and we vary the volume fractions of the  $11c^*$  solutions of the different polymers (ring DNA, linear DNA and dextran). By fixing the degree to which molecules overlap, we can unambiguously determine the effect of polymer topology (i.e., ring versus linear DNA), as well as steric and entropic interactions between distinct polymers (i.e., DNA and dextran), on the rheological properties and macromolecular dynamics. Specifically, we examine DNA-dextran blends with either purely linear DNA or 90-10 ring-linear DNA (which we abbreviate as ‘90-ring’ throughout the paper) at DNA volume fractions of  $\phi = 0$  (pure dextran solution), 0.25, 0.5, 0.75 and 1 (pure DNA solution).

#### 3.2 Bulk linear rheology of DNA-dextran composites

We first examine the bulk linear viscoelastic properties of DNA-dextran composites. Fig 2A compares the elastic modulus  $G'(\omega)$  and viscous modulus  $G''(\omega)$  for composites with linear DNA (left plot) and ring DNA (right plot) DNA. Pure dextran solutions (not shown) exhibit Newtonian properties with  $G'' \sim \omega^1$  scaling over the entire frequency range. Linear DNA solutions without dextran ( $\phi = 1$ ) show a transition from the terminal flow regime at low frequencies, with approximate scaling of  $G'' \sim \omega^1$  and  $G' \sim \omega^2$ , to a rubbery plateau at high frequencies with a crossover frequency, at which  $G'$  exceeds  $G''$ , of  $\omega_D \approx 0.25$  rad/s. This crossover frequency is a measure of the disengagement time,  $\tau_D \approx 2\pi/\omega_D \approx 25$  s, which is the relaxation time associated with an entangled polymer reptating out of its confining tube. Different from linear DNA, 90-ring DNA solutions ( $\phi = 1$ ) exhibit an elastic rubbery plateau over the entire frequency range, indicating very slow relaxation mechanisms at play ( $\tau > 100$  mins), as previously reported and predicted for nominally pure ring melts and ring-linear blends with low fractions of linear chains [12, 17, 25-28, 30].

This slow relaxation has also been predicted to arise in concentrated solutions of pure rings and those with linear ‘contaminants’ (as in our 90-ring solution) due to threading of rings by neighboring rings and linear chains, with the number of threading polymers increasing the threading lifetime [30, 31, 45]. Given the relatively small size of our rings ( $N=83$  where  $N$  is the number of Kuhn lengths  $l_k$ ) we do not expect a large number of threadings per ring [43]. As such,

because the threading lifetime for linear chains is predicted to be slower than that for rings, we expect that threading by the 10% linear chains plays an important role in the suppressed relaxation and extended rubbery plateau we observe.

**Figure 2. Bulk linear rheology of DNA-dextran composites exhibits complex dependence on the topology and volume fraction of DNA.** (A) Elastic modulus  $G'$  (closed symbols) and viscous modulus  $G''$  (open symbols) as a function of frequency  $\omega$  for DNA-dextran composites with linear DNA (left panel, triangles, dark shades) and 90-ring DNA (right panel, circles, light shades) at volume fractions of  $\phi = 0.25$  (orange), 0.5 (green) and 0.75 (cyan) and 1 (purple). Terminal regime scalings  $G'(\omega) \sim \omega^{-2}$  and  $G''(\omega) \sim \omega^{-1}$  are indicated by the scale bars in the left panel. (B) Loss tangent  $\tan \delta = G''(\omega)/G'(\omega)$  for data shown in (A). For clarity, pure DNA solutions ( $\phi = 1$ ) are denoted by open symbols. Dashed line denotes  $\tan \delta = 1$  which corresponds to low and high crossover frequencies,  $\omega_D = 2\pi/\tau_D$  and  $\omega_e = 2\pi/\tau_e$ , respectively. (C) Complex viscosity  $\eta(\omega) = [G''(\omega)^2 + G'(\omega)^2]^{1/2}/\omega$  of composites shown in (B) and a pure dextran solution ( $\phi = 0$ , red open squares). All composites exhibit complex viscosity thinning  $\eta(\omega) \sim \omega^{-\gamma}$  with exponents  $\gamma$  that vary from 0.65 to 0.88. (D) Plateau modulus  $G_N^0$  versus  $\phi$  for composites with 90-ring (circles, dashed connecting line) and linear (triangles, solid connecting line) DNA.  $G_N^0$  is computed by evaluating  $G'$  at the frequency in which  $\tan \delta$  is a minimum. (E) Zero-shear viscosity  $\eta_0 = \eta(\omega \rightarrow 0)$  versus  $\phi$  for composites with ring (circles, dashed connecting line) and linear (triangles, solid connecting line) DNA determined from  $\eta(\omega)$  curves shown in (C). (F) Complex viscosity thinning exponent  $\gamma$  versus  $\phi$  determined from power-law fits to the data shown in (C). Error bars are determined from fits to the data.

In contrast to previous studies on ring and linear polymer melts [19, 25], the magnitude of the plateau modulus  $G_N^0$  for 90-ring DNA is several times larger than that for linear DNA. To shed light on this discrepancy, we quantify  $G_N^0$  for all solutions by evaluating  $G'$  at the frequency at which the corresponding loss tangent  $\tan \delta = G''(\omega)/G'(\omega)$  (Fig 2B) is a minimum [98]. For cases in which a frequency-independent plateau is not apparent,  $G_N^0$  should be considered approximate. We find  $G_N^0 \simeq 3.24$  Pa and  $\sim 0.96$  Pa for 90-ring and linear DNA solutions, respectively, such that  $G_{N,R}^0/G_{N,L}^0 \simeq 3.4$  (Fig 2D). From  $G_N^0$  we can estimate the polymer length between entanglements  $l_e$  via  $l_e = 4cRT/5G_N^0M_{BP}$  where  $c$  is the mass concentration and  $M_{BP} \approx 650$  g/mol is the molecular weight of a DNA basepair ( $\sim 1/3$  nm) [8, 23]. For linear DNA, we find  $l_e \simeq 833$  nm and the number of entanglements per chain  $N_e \approx 10$ . As described in Methods, to maintain concentration at  $11c^*$ , the mass concentration of the nominal ring sample is  $\sim 3$ -fold higher than for the linear sample ( $11c_{90-R}^*/11c_L^* \simeq 2.42/0.78 \simeq 3.1$ ) due to the smaller  $R_G$  of rings. As  $l_e \sim c/G_N^0$ , the  $\sim 3$ -fold larger  $G_N^0$  and  $c$  for rings is consistent with the fact that we are fixing the degree of polymer overlap and thus  $l_e$ . Thus, while a  $\sim 3.4$ -fold higher  $G_N^0$  value is, at first glance, at odds with previous studies [19, 25, 36], the increased mass concentration of our 90-ring solutions compared to our linear DNA solutions accounts for this increase.

Upon mixing DNA with dextran (thereby decreasing  $\phi$ ), we find that the dependence of  $G_N^0$  on DNA topology is substantially reduced, with values for 90-ring and linear composites differing by  $\leq 1.5x$ . Future studies will focus on the  $\phi > 0.75$  regime to determine the onset of more pronounced topology dependence of  $G_N^0$ , as seen in pure DNA solutions ( $\phi = 1$ ). Comparing the effect of varying  $\phi$  on the 90-ring and linear DNA, we find that  $G_N^0$  decreases for 90-rings when mixed with dextran, while for linear DNA,  $G_N^0$  displays a non-monotonic dependence on  $\phi$  with a maximum at  $\phi = 0.75$ .

For both topologies,  $\phi \leq 0.5$  blends display a high frequency crossover  $\omega_e$  in which  $G'' > G'$ , which is a measure of the entanglement time  $\tau_e \approx 2\pi/\omega_e$  or the time it takes for an entangled polymer to ‘feel’ its tube confinement [8]. This crossover frequency increases from  $\sim 0.63$  at  $\phi = 0.25$  to  $\sim 25$  rad/s at  $\phi = 0.5$ , independent of DNA topology, and is non-existent for  $\phi = 0.75$  and 1 (implying  $\omega_e > 100$  rad/s). These values correspond to  $\tau_e \approx 10$  s, 0.25 s and  $< 0.06$  s, for  $\phi = 0.25, 0.5$  and  $> 0.5$ . The independence of  $\tau_e$  on topology can be understood as arising from the matching of  $l_e$ . Namely,  $\tau_e \sim a^4/D_0R_{G,0}^2$  where  $a \approx (l_K l_e)^{1/2}$  is the entanglement tube diameter,  $l_K$  is the Kuhn length ( $\sim 100$  nm for dsDNA), and  $D_0$  and  $R_{G,0}$  are the diffusion coefficient and radius of gyration in the dilute limit [8, 23, 99]. Insofar as  $D_{0,R}/D_{0,L} \approx 1.32$ ,  $R_{G,0,L}/R_{G,0,R} \approx 1.58$  [87], and  $l_{e,L} \approx l_{e,R}$ , we find  $\tau_{e,R} \approx 1.8\tau_{e,L}$ ; such that, within the factor of 2 frequency resolution of our measurements, we can estimate  $\tau_{e,R} \approx \tau_{e,L}$ .

Further, if we only consider the DNA in the composites, and use the relations  $\tau_e \sim l_e^2$ ,  $l_e \sim c/G_N^0$  and  $G_N^0 \sim c^2$  [8], it follows that  $l_e$  decreases as  $\phi$  increases (i.e.,  $l_e \sim c^{-1} \sim \phi^{-1}$ ) so  $\tau_e$  is likewise expected to decrease, as we find in composites. The decrease in  $\tau_e$  between  $\phi = 0.25$  and  $0.50$  is stronger than the predicted scaling (i.e.,  $\tau_e \sim l_e^2 \sim \phi^{-2}$ ), with an approximate scaling of  $\tau_e \sim \phi^{-5.3}$ .

This increased  $\phi$  dependence may indicate that dextran increases the entanglement density and overlap of DNA via depletion interactions, which would cause  $l_e$  to decrease more strongly than expected with increasing  $\phi$ . An alternative explanation is that the  $\phi = 0.25$  and  $\phi = 0.50$  composites span different scaling regimes [100]. While  $G_N^0 \sim \phi^2$  generally holds for entangled flexible linear polymers, semidilute solutions of flexible and semiflexible linear chains are predicted to follow a steeper scaling  $G_N^0 \sim \phi^{9/4}$  which leads to a stronger  $\phi$  dependence of  $\tau_e$ :  $\tau_e \sim l_e^2 \sim (\phi^{-5/4})^2 \sim \phi^{-5/2}$ . At low  $\phi$  values (0.25 and 0.5), ignoring the effect of dextran, the DNA is indeed in the semidilute limit so this steeper scaling may likely apply.

Moreover, in the semidilute model,  $G_N^0$  also increases with increasing Kuhn length  $l_k$ , such that  $G_N^0 \sim \phi^{9/4} l_k^{19/4}$  and  $G_N^0 \sim \phi^{9/4} l_k^{11/4}$  for flexible and semiflexible polymers, respectively. Depletion-driven bundling of DNA by dextran, facilitated by the previously reported dextran-mediated elongation of linear DNA from random coil configuration [74], could indeed serve to ‘stiffen’ the (bundled) DNA (i.e., reduce its susceptibility to thermal bending), thereby increasing  $l_k$  and pushing the flexible DNA towards the semiflexible regime. Within this framework, we expect  $\tau_e \sim l_e^2 \sim (\phi/G_N^0)^2 \sim (\phi^{-5/4} l_k^{-11/4})^2$ , with  $l_k$  increasing with increasing  $\phi$  as DNA overlap and bundling increases (and the entanglement spacing decreases). For semiflexible polymers the mesh size, which scales as  $\xi \sim \phi^{-1/2}$  [101], provides a measure of this entanglement spacing [102]. As such, keeping all other scaling assumptions, and phenomenologically estimating  $l_k \sim \xi^{-1} \sim \phi^{1/2}$ , provides  $\tau_e \sim \phi^{-5/2} l_k^{-11/2} \sim \phi^{-5/2} \phi^{-11/4} \sim \phi^{-5.3}$ , matching our empirical scaling. We note that this scaling argument should not be considered quantitative as it draws on theoretical assumptions that span different regimes, and the empirical scaling is determined from two data points. Nevertheless, the scaling arguments indicate that dextran-mediated interactions likely play a principal role in the steep scaling we see at low  $\phi$  by increasing the DNA entanglement density and stiffness (i.e., reducing  $l_e$  and increasing  $l_k$ ) by elongation and small-scale bundling.

To incorporate the effect of the dextran, we use our estimated  $G_N^0$  values (Fig 2D), along with  $l_e \sim \phi/G_N^0$  and  $l_{e,DNA} \approx 833$  nm, to estimate  $l_e$  for the different composites. This analysis (Fig S3) shows that, for linear DNA, the  $\phi = 0.75$  composites have the smallest predicted  $l_e$  ( $\sim 300$  nm), whereas for rings,  $\phi = 1$  solutions have the lowest ( $\sim 833$  nm). Taken together, these results suggest that the peak in  $G_N^0$  at  $\phi = 0.75$  for linear DNA may be due to dextran-mediated DNA self-association and increased DNA overlap. However, this effect appears to play a lesser role for 90-ring DNA, as it reaches the highest apparent degree of overlap (i.e., minimum  $l_e$ ) without dextran ( $\phi = 1$ ).

Further examination of the loss tangent (Fig 2B) shows that, for linear DNA composites, the rubbery plateau, flanked by the low and high frequencies at which  $\tan \delta = 1$  (i.e.,  $\omega_D$  and  $\omega_e$ ) shifts to longer timescales (lower  $\omega$ ) and extends over a wider  $\omega$  range when mixed with dextran. We also see that  $\tan \delta$  generally increases with  $\omega$  for  $\phi \leq 0.5$  composites whereas the opposite is true for  $\phi > 0.5$ . This qualitatively different  $\omega$  dependence is reminiscent of the difference between rheological properties of extended semiflexible polymers, such as actin filaments, which

exhibit solid-like behavior at low  $\omega$  and viscous-dominated flow at high  $\omega$  [103], compared to entangled flexible random coil polymers (e.g., DNA) which display low- $\omega$  flow and high- $\omega$  rubber-like elasticity. This effect may indicate that dextran polymers are acting as depletants to extend and bundle linear DNA molecules, making them more akin to extended semiflexible polymers, as we suggest above [68, 72, 75]. As the DNA concentration increases and the dextran concentration decreases the depletion-driven bundling becomes weaker while DNA-DNA entanglements are more abundant, so the frequency dependence is more akin to that of flexible polymers but the modulus is higher. Thus, the maximum in  $G_{N,L}^0$  at  $\phi = 0.75$ , suggests an optimal combination of DNA overlap and depletion-driven stretching and bundling. Below  $\phi = 0.75$ , the DNA in the composite has fewer entanglements (Fig S3), so reinforcement from bundling comes at the cost of losing connectivity, thereby reducing  $G_{N,L}^0$ . We note that while we expect bundling to play a primary role in the rheology we measure, we expect bundles to be limited to only a few DNA chains, such that high connectivity is preserved at  $\phi = 0.75$ . This small-scale bundling would be below the resolution limit of our imaging setup (see Methods), similar to actin bundling reported in actin-DNA composites [60].

For 90-ring composites, the rubbery plateau is truncated at short times (high  $\omega$ ) in  $\phi = 0.25$  and 0.5 composites compared to  $\phi = 0.75$  and 1 cases in which the plateau regime fully spans over four decades. Further, compared to linear DNA composites, there is limited  $\phi$  dependence at low  $\omega$ , suggesting that stiffening of rings via bundling and/or elongation play minimal roles in 90-ring composites. We suggest instead that the variation in threading propensity of rings dominates the rheology for ring composites. Previously, we found that high dextran concentrations ( $>10c^*$ ) led to compaction of ring DNA, rather than elongation [75], which would result in fewer entanglements and more viscous-dominated rheology compared to a ring DNA solution at the same degree of overlap, as shown in Fig 2A. Further, due to  $>10\times$  smaller coil size of dextran compared to DNA rings, the ability for dextran to kinetically pin rings via long-lived threading events is likely minimal.

Indeed, rings in a melt of short (unentangled) polymer chains have been shown to diffuse faster than when in their own melts, and adopt more swollen conformations due to the interpenetrating linear chains [54]. It is important to clarify that in this regime the short linear chains are, in fact, threading the rings, but the effect of threading is to swell the rings and reduce the local chain density due to chain-end effects, thereby increasing, rather than decreasing, ring mobility. Threading by linear chains only slows the DNA when the threading linear chains become long enough to be sufficiently entangled, which is not the case for our high  $\phi$  (i.e., low dextran fraction) 90-ring composites.

Such swelling, which may occur for higher DNA volume fractions (versus compaction observed for higher dextran fractions), likely facilitates ring-ring and ring-linear DNA threading in composites that suppress relaxation. Swelling will also limit the fraction of double-folded and amoeba-like ring conformations that can undergo modified reptation but are not threaded [21, 104]. Thus, in the  $\phi = 0.75$  ring composite the relaxation is likely entirely due to constraint release of

threaded DNA, while the  $\phi = 1$  DNA solution has both reptation and threading contributions. This effect can be seen in Fig 2B in which  $\tan \delta$  for the  $\phi = 0.75$  ring composite is smaller than that for  $\phi = 1$  over most of the frequency range ( $\omega \approx 0.006 - 6$  rad/s), indicating the timescale over which threading, which occurs more frequently at  $\phi = 0.75$  than  $\phi = 1$ , dominates ( $t_{th} \approx 1$  to  $\sim 10^3$  s). Above and below this timescale, unthreaded and unswollen rings in  $\phi = 1$  solutions may still ‘feel’ the constraints of the entanglement tube (no measurable  $\tau_e$ ) and be confined to reptate within it (no measurable  $\tau_D$ ).

Finally, we evaluate the complex viscosity  $\eta(\omega)$  (Fig 2C), and, assuming that the Cox-Merz rule is valid for our solutions [16, 18, 47, 105-107], we estimate the zero-shear viscosity  $\eta_0 = \eta(\omega \rightarrow 0)$  (Fig 2E) and corresponding thinning exponent  $\gamma$  (Fig 2F) by fitting each curve to a power-law  $\eta(\omega) \sim \omega^{-\gamma}$ . Because only the linear DNA solution and  $\phi=0.25$  90-ring composite exhibit low-frequency plateaus, our  $\eta_0$  values for the other cases should be taken as lower limits. As shown in Fig 2D we find that  $\eta_0$  for linear DNA composites exhibit a non-monotonic dependence on  $\phi$ , corroborating our interpretation of depletion-driven stretching and bundling of linear DNA in composites.

Conversely, for 90-rings,  $\eta_0$  increases monotonically with  $\phi$ , in agreement with previous studies showing that dilute rings in a melt of short linear chains (akin to low  $\phi$  composites) have lower viscosity than for pure rings [54]. Further  $\eta_0$  is maximum at  $\phi=1$  rather than  $\phi = 0.75$  because  $\eta_0$  is evaluated in the long-time limit, such that  $t > t_{th}$ , so threading events are no longer constraining the rings but tube confinement is still present, as indicated by Fig 2B. The latter is more prevalent for  $\phi=1$  90-ring solutions compared to  $\phi = 0.75$  composites.

We next examine the complex viscosity thinning exponents (Fig 2F), which provide insight into the ability of entangled polymers to align with flow [18, 108, 109]. For highly entangled linear polymer melts,  $\eta(\omega) \sim \omega^{-1}$ , while thinning exponents of  $\gamma \approx 0.6 - 0.9$  have been reported for solutions of entangled linear DNA [16, 20]. Previous studies on entangled rings report reduced thinning exponents of  $\gamma \approx 0.4 - 0.6$  [16, 20], owing to the reduced ability of rings to stretch along the shear direction. Our previous studies on ring-linear DNA blends showed a maximum in  $\gamma$  with comparable concentrations of rings and linear chains, in which threading by linear chains was most pervasive, suggesting that threading by linear chains facilitates flow alignment of rings [16]. Moreover, if we assume rings are compacted by dextran at low  $\phi$  while linear chains are stretched and bundled, we would expect minimal flow alignment and thinning for rings and maximal alignment for linear chains at  $\phi=0.25$  and  $0.5$ , which is indeed what we see. For  $\phi > 0.5$ ,  $\gamma$  drops significantly for linear DNA composites whereas it increases a comparable amount for 90-ring DNA composites. Thus, for rings, threading by linear chains, mediated by chain swelling, appears to promote thinning whereas for linear chains it is the depletion-driven elongation and increased overlap.

### 3.2 Differential Dynamic Microscopy to determine macromolecular transport properties

To shed light on the macromolecular dynamics that give rise to the bulk rheological properties discussed above, we use an optical microscopy attachment to our rheometer to collect time-series of images of diffusing linear and ring DNA in the composites (Fig S2), and perform DDM analysis on the time-series to determine their transport properties (Fig 3) [110, 111]. Importantly, these data are collected in the exact samples and geometry as bulk rheology data immediately before and after rheology measurements (see Methods).

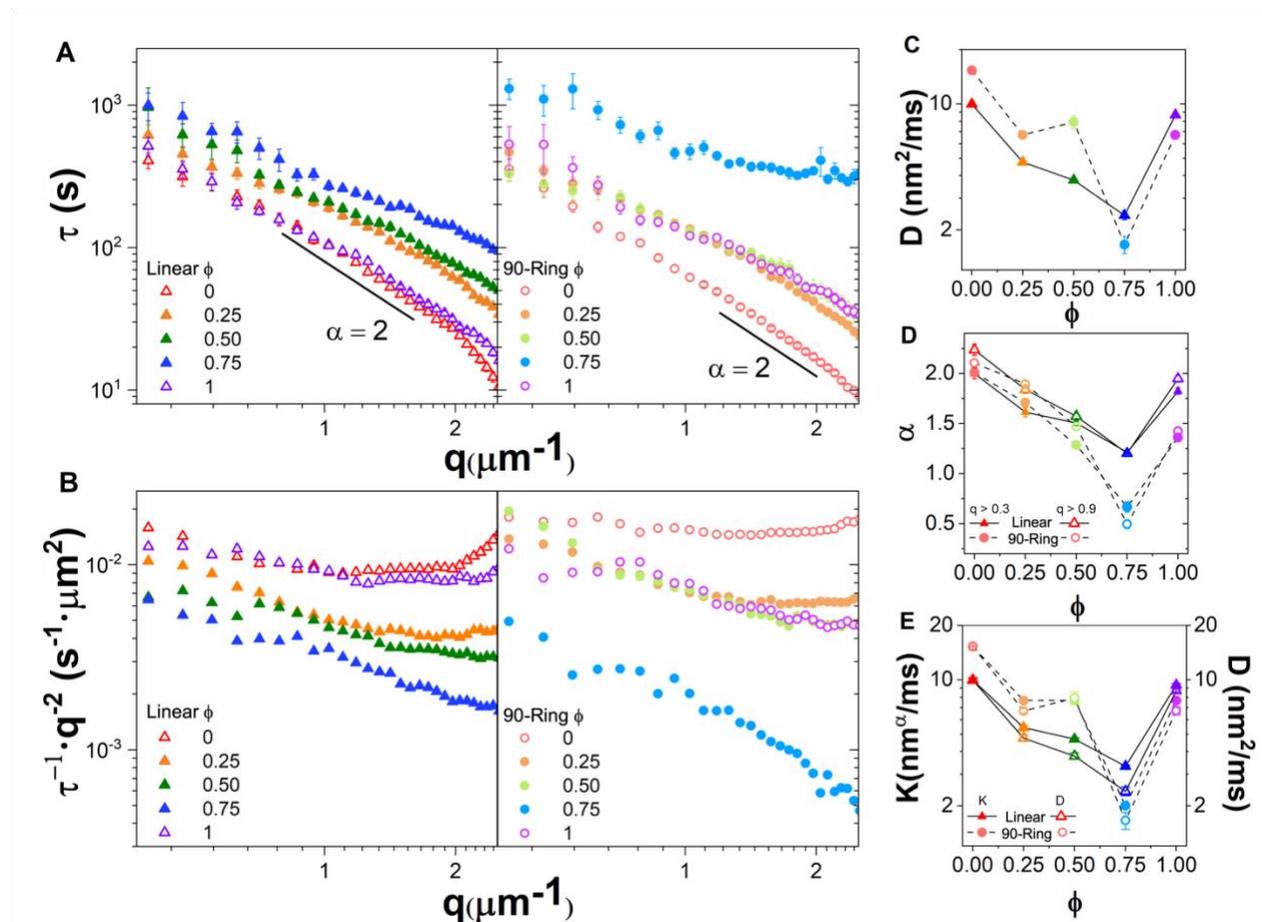

Some key questions we seek to answer with this analysis are: (1) if ring DNA solutions and composites exhibit glassy dynamics, (2) if mixing of linear DNA with dextran slows its diffusion and/or alters its transport properties, (3) the extent to which the relaxation and diffusive mechanisms that rings and linear chains exhibit in the different conditions are similar or different, and (4) if the topology and  $\phi$  dependence of bulk rheological properties manifest at the molecular level or if there are scale-dependent phenomena that arise, as seen in other entangled polymer solutions and composites [47, 84, 112-114].

Fig 3A shows the characteristic decorrelation times  $\tau$  of diffusing DNA polymers versus wavenumber  $q$ , which we determine by fitting the radially-averaged image structure function  $D(q, \Delta t)$  to a stretched exponential, as described in Methods. In general, higher  $\tau$  values for a given  $q$  indicate slower motion. By fitting  $\tau(q)$  to the power-law function  $\tau = 1/(Kq^\alpha)$ , one can determine the type of motion. Normal Brownian diffusion is described by  $\alpha = 2$  with  $K$  equating to the corresponding diffusion coefficient  $D$ . We can therefore estimate diffusion coefficients for our data by fitting each curve to  $\alpha = 2$  scaling (Fig 2C). Conversely, restricted or halted motion, such as in glassy systems, often results in much weaker  $q$  dependence ( $\alpha \rightarrow 0$ ) as we see in some of the data (Fig 3D) [96, 97]. If  $\alpha$  deviates from 2 then  $K$  is a generalized transport coefficient with dimensions that depend on  $\alpha$  (Fig 3E).

For both DNA topologies, transport is fastest (smallest  $\tau$ ) and scaling is closest to diffusive ( $\alpha = 2$ ) in dextran solutions ( $\phi=0$ ), and is slowest and exhibits the weakest dependence in  $\phi=0.75$  composites. To better visualize the deviation from normal diffusion and the non-monotonic  $\phi$  dependence shown in Fig 3A, we plot  $1/\tau q^2$  (Fig 3B), which, for diffusive transport, is a horizontal line with a  $y$ -intercept equal to  $D$  (Fig 3C). Halted transport or kinetic arrest manifests as a negative slope approaching  $\alpha-2 \approx -2$ , as seen for  $\phi=0.75$  90-ring composites. Such kinetically arrested states, observed in simulations of entangled ring polymer solutions [31], indicate ring-ring and ring-linear threading events.

It may be possible that ring DNA is threaded by dextran polymers. However, the much smaller size of dextran polymers compared to DNA rings would limit their ability to halt ring diffusion by maintaining long-lived threadings. Indeed, as previously observed in ring-linear melts, interpenetration (i.e. threading) by short linear polymers (akin to the dextran used here) cause tracer rings to swell and diffuse faster than when in their own melts [54]. Dextran-mediated

swelling at  $\phi = 0.75$  could facilitate DNA-DNA threading events responsible for glassy behavior, by reducing the fraction of double-folded and collapsed rings [21].

**Figure 3. Differential dynamic microscopy of DNA-dextran composites shows arrested dynamics and non-monotonic dependence on the volume fraction of DNA.** (A) Characteristic decay time  $\tau$  versus wave vector  $q$  for DNA-dextran composites with linear DNA (left panel, triangles, dark shades) and 90-ring DNA (right panel, circles, light shades) at volume fractions of  $\phi = 0$  (red),  $\phi = 0.25$  (orange), 0.5 (green) and 0.75 (cyan) and 1 (purple). Scaling bars indicate diffusive dynamics, i.e.,  $\tau(q) \sim q^{-2}$ . (B) Data shown in (A) plotted as  $\tau^{-1}q^{-2}$ , which equates to a  $q$ -independent diffusion coefficient  $D$  for systems that exhibit normal diffusion. Increased negative slopes indicate more arrested or halted motion. (C) Diffusion coefficient versus  $\phi$  for composites with 90-ring (circles, dashed connecting line) and linear (triangles, solid connecting line) DNA determined by fitting the data in A to  $\tau(q) = 1/(Dq^2)$ . (D) Transport scaling exponent  $\alpha$  versus  $\phi$  for composites with 90-ring (circles, dashed connecting line) and linear (triangles, solid connecting line) DNA determined from fitting the data in A to  $\tau(q) = 1/(Kq^\alpha)$ . Fits are performed over the entire  $q$  range shown (filled symbols) and for  $q > 0.9$  (open symbols).  $q=2$  signifies normal diffusion and  $q \rightarrow 0$  indicates kinetic arrest. (E) Generalized transport coefficient  $K$  (left axis, filled symbols) compared to the corresponding diffusion coefficient  $D$  (right axis, open symbols) versus  $\phi$  for composites with ring (circles, dashed connecting line) and linear (triangles, solid connecting line) DNA determined from fitting the data in (A) to  $\tau(q) = 1/(Kq^\alpha)$  or  $\tau(q) = 1/(Dq^2)$ . Error bars (many of which are too small to see) are determined from fits to the data.

These results corroborate our bulk rheology data that suggests that ring threadings are most pervasive and long-lived at  $\phi=0.75$ . Conversely,  $\phi=1$  and  $0.5$  ring composites exhibit  $q$ -dependence that is in between diffusive and arrested ( $\alpha \approx 1.4$ ) (Fig 3D), indicative of contributions from populations of both diffusive entangled rings and halted threaded rings—as our rheology results suggest.

Linear DNA composites exhibit similar trends, with minimum  $\alpha$  and  $D$  values at  $\phi=0.75$ , followed by  $0.5$ , but the variation in  $\alpha$  with  $\phi$  is much weaker (Fig 3C,D). This weaker  $\phi$ -dependence for linear chains is more evident when we evaluate the generalized transport coefficients  $K$  for the different composites:  $K$  exhibits a weaker  $\phi$  dependence for linear chains than the corresponding diffusion coefficient (Fig 3E). Further, the pure linear DNA solution exhibits diffusive scaling ( $\alpha \approx 2$ ), in contrast to the 90-rings ( $\alpha \approx 1.4$ ). These topology-dependent effects highlight the distinct relaxation mechanisms at play in the different composites. Namely, threading dominates 90-ring composites whereas depletion-driven DNA elongation and bundling mediate the restricted diffusion in linear DNA composites.

These different transport modes are expected to have different degrees of heterogeneity [39, 115], which we evaluate by examining the spread in the intermediate scattering functions (ISF) generated from DDM performed on different ROIs in the time-series (Fig S5). In general, the spreads in the ISFs for 90-ring composites are larger than that for linear composites, in line with simulations that show that entangled ring polymer solutions with glassy dynamics exhibit heterogeneous transport [30, 31]. Moreover, considering the 90-ring composites at short lag times ( $\Delta t \lesssim 100$  s), the spread in the ISFs for  $\phi=0.5$  and  $1$  are significantly broader than that for  $\phi=0.75$ . This variation indicates that over small timescales the dynamics of the  $\phi=0.75$  composite is dominated by a single mechanism (i.e., long-lived threading), whereas for  $\phi=0.5$  and  $\phi=1$  composites, a combination of faster modes (i.e., short-lived threading, single-chain threading, modified reptation), not prevalent at  $\phi=0.75$ , also contribute to the dynamics.

While threading alone, by rings or linear chains, is predicted to result in heterogeneous transport, this heterogeneity is predicted to increase as  $\Delta t$  increases [30]. At short lag times, below the average threading lifetime, there should be much less heterogeneity as all rings are kinetically arrested by threadings [30]. This effect is what we see for 90-rings in Fig S5. Namely,  $\phi=0.75$  exhibits the broadest distribution of all ISFs for  $\Delta t \gtrsim 200$  s, whereas the spreads in ISFs for  $\phi=0.5$  and  $\phi=1$  are much broader for  $\Delta t \lesssim 200$  s. Importantly, delayed onset of heterogeneity, as we see for  $\phi=0.75$ , is expected to be more pronounced when rings are threaded by multiple chains [30, 34], which we expect to be the case in the  $\phi=0.75$  composite, in which swelling facilitates threading. In contrast, heterogeneity associated with a combination of single-threaded, multi-threaded and double-folded rings, as we expect for  $\phi=0.5$  and  $\phi=1$ , should manifest more strongly at shorter lag times as the associated relaxation timescales are shorter.

Finally, we note that the scaling of  $\tau(q)$  is weaker at smaller  $q$  values (i.e., longer lengthscales  $\lambda$ ), as depicted by comparing  $\alpha$  values computed over the entire  $q$  range ( $q = 2\pi/\lambda \approx 0.3 - 2.5$

$\mu\text{m}^{-1}, \lambda \approx 2.5 - 20 \mu\text{m}$ ) to those excluding  $q_c \lesssim 0.9 \mu\text{m}^{-1}$  ( $\lambda_c \gtrsim 7 \mu\text{m}$ ) (Fig 3D). We can understand this effect and the corresponding lengthscale  $\lambda_c$  as arising from entanglements and threadings that hinder polymer motion beyond a few entanglement lengths  $l_e$  [39, 116], such that restricted transport ( $\alpha \rightarrow 0$ ) will be more apparent for  $\lambda > 0(l_e)$ . Indeed, Fig S3 shows that the range of  $l_e$  values for the different composites span from  $\sim 0.3 \mu\text{m}$  (for linear  $\phi=0.75$ ) to  $20 \mu\text{m}$  (for ring  $\phi=0.25$ ), on the order of  $\lambda_c$ , corroborating this interpretation.

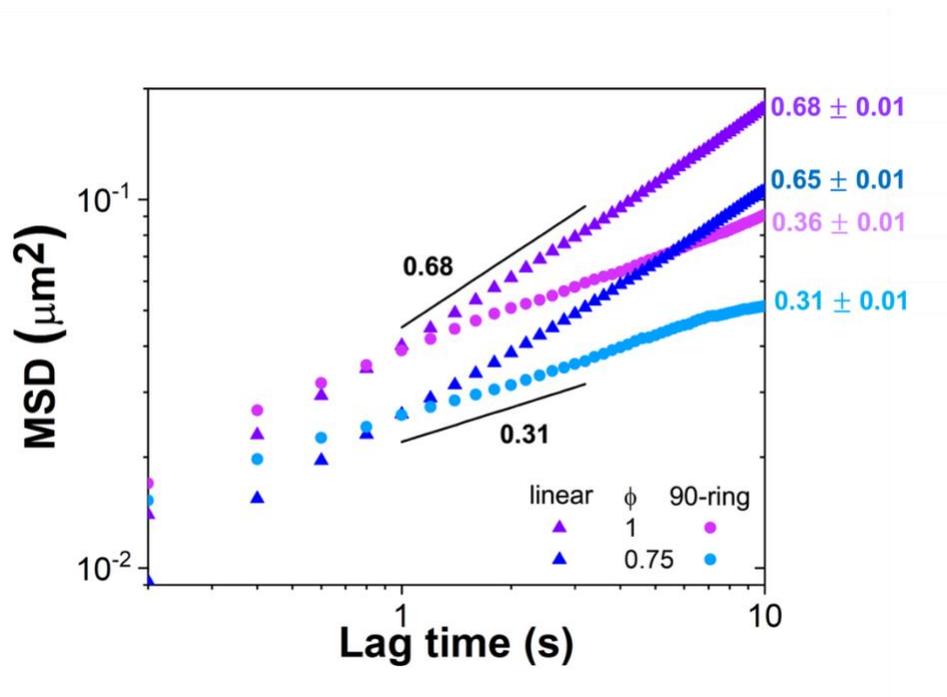

### 3.3 Single-molecule tracking to corroborate DDM and expand the spatiotemporal scales of transport measurements

To further understand the non-monotonic dependence of transport and rheology on  $\phi$ , and the  $\phi$ -dependent differences between 90-ring and linear DNA, we perform single-molecule tracking (SMT) measurements of DNA in  $\phi = 0.75$  and  $\phi = 1$  composites. We focus on  $\phi = 0.75$  as it deviates most strongly from normal diffusive scaling for both topologies. Fig 5 shows the center-of-mass mean-squared displacements (*MSD*) versus lag time  $\Delta t$  for ring and linear DNA at  $\phi = 0.75$  and 1. All cases exhibit anomalous subdiffusion, i.e.,  $MSD \sim \Delta t^\beta$  where  $\beta < 1$ . For both  $\phi$  values, rings display greater deviation from normal diffusion compared to linear DNA, with an average value of  $\beta \approx 0.34$  compared to  $\sim 0.67$  for linear chains.

These  $\beta$  values are comparable to, but slightly lower than, those previously reported for tracer ring and linear DNA molecules in networks of cytoskeleton filaments [39, 113, 116]. In those experiments the lower  $\beta$  value for rings was attributed to threading by cytoskeleton filaments, further supporting our interpretation of the results shown in Figs 2 and 3. Moreover, Ref [74] reported anomalous scaling exponents of  $\beta \approx 0.75$  and  $\sim 0.72$  for 11 kbp and 115 kbp linear DNA in  $\sim 10c^*$  dextran solutions for  $\Delta t \lesssim 10$  s (the upper-limit of our SMT measurements) after which normal diffusion is observed. These exponents are similar but higher than our SMT-measured  $\beta \approx 0.65$  for the  $\phi=0.75$  linear DNA composite, suggesting that DNA elongation is likely a principal contributor to the dynamics we measure, but that an additional contribution which would reduce the scaling exponent further, such as multi-filament bundling, also plays an important role. Moreover, in contrast to Ref [74], deviation from normal diffusion for the  $\phi=0.75$  linear case is evident in our DDM measurements, which span  $\Delta t = 10 - 1000$  s, further suggesting an additional slow contribution to the DNA relaxation.

Conversely, previous SMT experiments of tracer (i.e.,  $\phi = 0$ ) 115 kbp ring and linear DNA crowded by  $\sim 4-14c^*$  dextran solutions, reported normal diffusion for  $\Delta t \gtrsim 10$  s [74, 75]. This result, which aligns with our DDM measurements (which span  $\Delta t \approx 10-1000$  s) for  $\phi = 0$  (Fig 3), supports our conclusions that (i) threading by dextran does not contribute to the phenomena we report here for 90-rings, and (ii) bundling of linear DNA (not seen in Refs [74, 75]) plays a key role in the observed subdiffusion of linear DNA in composites above a critical fraction of DNA, in particular at longer lag times. Depletion-driven elongation of the linear DNA, as reported in Refs [74, 75], likely facilitates nematic DNA bundling, by extending DNA from random coil configurations to extended conformations similar to those of semiflexible polymers such as actin

filaments. Further, previous studies on entangled actin solutions [117, 118], have reported similar subdiffusive  $\beta$  exponents to those for our linear DNA composites, supporting our interpretation that bundling, which serves to stiffen the DNA (i.e., increasing  $l_k$ ), underlies the hindered diffusion and increased elasticity of linear DNA-dextran composites compared to  $\phi = 1$  DNA solutions.

**Figure 4. Ring and linear DNA exhibit topology-dependent subdiffusion at high DNA volume fractions.**  $MSD$  versus lag time  $\Delta t$  for linear (triangles) and 90-ring (circles) DNA diffusing in composites with DNA volume fractions of  $\phi = 1$  (dark and light purple) and  $\phi = 0.75$  (dark and light blue). Black lines represent power-law scaling with exponents listed. The exponent  $\beta$  from fitting each curve to  $MSD \sim \Delta t^\beta$  is listed to the right of each curve. In all cases, DNA exhibits subdiffusion ( $\beta < 1$ ) with rings displaying greater deviation from normal diffusion ( $\beta = 1$ ) than linear DNA. For both topologies  $MSDs$  are  $\sim 2\times$  lower in  $\phi = 0.75$  composites compared to  $\phi = 1$ .

We further point out that  $\beta$  is slightly lower (outside of measured error) for  $\phi = 0.75$  compared to  $\phi = 1$  for both topologies, and the value of the  $MSD$  at a given  $\Delta t$  is  $\sim 2$ -fold lower, in line with our DDM and bulk rheology data. The strongly anomalous diffusion and concomitantly low  $MSD$  for 90-rings at  $\phi = 0.75$  corroborate our interpretation of glassy dynamics due to ring-ring and ring-linear threadings that pin rings in kinetically-arrested states. Further, as such glassy dynamics are predicted to be accompanied with heterogeneous transport, we evaluate the van Hove displacement distributions from our SMT measurements for lag times  $\Delta t = 1-15$  s (see Fig S6), which span the first decade of DDM lag times shown in Fig S5. The distributions display non-Gaussian exponential tails, similar to those reported in Ref 30, that indicate heterogeneous transport. The composites with the most non-Gaussian distributions correlate with those that show the most spread in the ISFs for  $\Delta t < 40$  s (i.e.,  $\phi = 1$  for ring and linear DNA) (see Fig. S5). For

larger  $\Delta t$  ( $>100$  s), outside our SMT measurement range, we expect the trend to flip such that the  $\phi = 0.75$  composites, which display the widest spreads in ISFs for  $\Delta t > 100$  s, to exhibit the most pronounced non-Gaussianity.

Finally, as we discuss above, that the timescale probed by SMT is lower than for DDM (Fig 1B), corresponding to  $\omega \simeq 0.6 - 30$  rad/s. In this range, the linear DNA solution ( $\phi=1$ ) exhibits more elastic-like behavior compared to lower frequencies, probed by DDM, in which it exhibits terminal flow behavior. As such, DDM measurements show  $\phi = 1$  linear DNA obeying normal Brownian diffusion ( $\alpha \approx 2$ ) while SMT experiments measure subdiffusive transport.

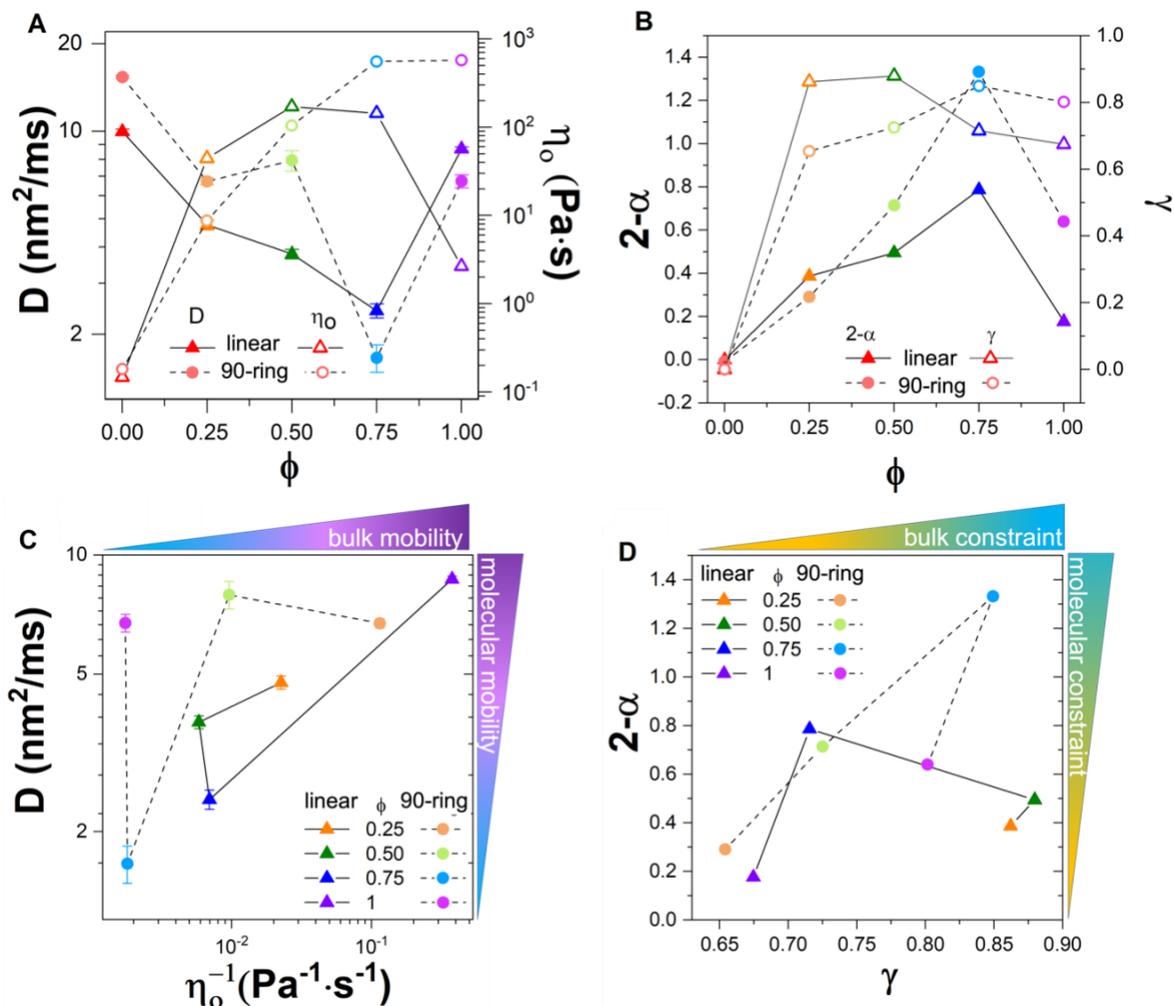

### 3.4 Coupling bulk rheological properties to macromolecular dynamics

To quantitatively compare and couple bulk and molecular-level dynamics we compare the diffusion coefficient determined from DDM (Fig 3D) to the zero-shear viscosity measured via bulk rheology (Fig 2E). In Newtonian fluids (as well as some non-Newtonian fluids) these quantities are inversely related via the Stokes-Einstein fluctuation-dissipation relation, such that  $D$  vs  $\eta_0^{-1}$  should exhibit linear scaling, provided the size and conformation of the polymers are not changing. As shown in Fig 5A, we find that, in general, higher diffusion coefficients are coupled to lower viscosities, as we may expect.

To better visualize and quantify the relation between  $D$  and  $\eta_0^{-1}$ , which are measures of mobility on the molecular scale and bulk scale, respectively, we plot the phase map of  $(D, \eta_0^{-1})$  combinations (Fig 5C). Data points in the lower-left and upper-right of the plot correspond to nearly immobile and highly mobile systems, respectively, across scales. It is clear that the  $\phi=0.75$  ring composite is the least mobile and the  $\phi=1$  linear DNA is the most mobile across all scales. Conversely, data points that are aligned horizontally or vertically indicate systems in which mobility only appears to change at the bulk or molecular scale, respectively. For example, 90-ring composites with  $\phi=0.25$ , 0.5 and 1 have nearly identical diffusion coefficients, yet the corresponding  $\eta_0^{-1}$  values increase by two orders of magnitude as  $\phi$  increases. This result suggests that similar molecular-scale mechanisms dictate the diffusion of individual DNA molecules across the different composites; however, the bulk mobility increases as  $\phi$  increases.

In Fig 5B, we examine the bulk complex viscosity thinning exponent  $\gamma$  and the deviation of the DDM transport coefficient from diffusive dynamics, which we define as the quantity  $2-\alpha$ , as a function of  $\phi$  (Fig 5B). Both metrics quantify constraint, with  $\gamma$  ranging from 0 for Newtonian fluids to 1 for highly entangled or threaded systems and  $2-\alpha$  spanning from 0 for normal Brownian diffusion to 2 for arrested dynamics. As such, we expect the dependence of  $\gamma$  and  $2-\alpha$  on  $\phi$  and topology to track with one another, corresponding to data points populating the lower-left (minimal constraints) and upper-right (many constraints) of the phase map shown in Fig 5D. This relationship loosely holds for many of the composites, with the  $\phi=0.75$  90-ring composite appearing the most constrained (top-right) and the  $\phi=1$  linear composite exhibiting negligible constraints (bottom-left) across all scales. However, we also find cases, such as  $\phi=0.25$  and 0.5

linear DNA composites, that appear highly entangled and constrained at the bulk scale (righthand side of the plot), while displaying relatively little deviation from diffusive scaling at the molecular scale (bottom portion of the plot).

**Figure 5. Coupling of bulk and molecular-level metrics reveals emergent scale-dependent dynamics in DNA-dextran composites.** (A) Diffusion coefficient  $D$  determined from DDM (left axis, closed symbols) and zero-shear viscosity  $\eta_0$  (right axis, open symbols) determined via bulk rheology for DNA-dextran composites with linear (triangles) or 90-ring (circles) DNA at varying DNA volume fractions  $\phi$ . (B) Deviation from diffusive DDM scaling, quantified by  $2-\alpha$  (left axis, closed symbols), and complex viscosity thinning exponent  $\gamma$  (right axis, open symbols) determined via bulk rheology versus  $\phi$  for DNA-dextran composites with linear (triangles) and ring (circles) DNA. (C) Data shown in (A) plotted as  $D$  versus  $\eta_0^{-1}$  for DNA-dextran composites with 90-ring (circles, dashed connecting line) and linear (triangles, solid connecting line) DNA. Both quantities are measures of mobility with larger values indicating higher mobility, as indicated by the gradients. (D) Data shown in (B) plotted as  $2-\alpha$  versus  $\gamma$  for DNA-dextran composites with ring (circles, dashed connecting line) and linear (triangles, solid connecting line) DNA. Both quantities are indicators of steric constraints with larger values indicating more constrained dynamics, as indicated by the gradients.

Finally, the data in Figs 5C,D show that  $\phi=0.25$  linear DNA composites have increased bulk  $\eta_0$  and  $\gamma$  values and reduced microscale  $D$  and  $\alpha$  values compared to  $\phi=1$  linear DNA solutions, while the opposite is true of all metrics for 90-rings. We understand this effect as arising from the loss of DNA-DNA threadings which, when present, lead to kinetically arrested states that suppress bulk dissipation. Further, dextran solutions at sufficiently high volume fractions (comparable to  $\phi \leq 0.5$  composites) have been shown to compact ring DNA which would serve to reduce entanglements with neighbors at low DNA concentration. Indeed, we show that  $l_e$  for rings at  $\phi=0.25$  is greater than the DNA contour length  $L$  and greater than that computed assuming  $l_e \sim \phi^{-1}$  scaling, indicating that compaction and reduced entanglements dictate ring dynamics at low  $\phi$ . Conversely, recent work demonstrates that rings are swollen by transient threading of linear polymers that are below the entanglement threshold (such as in our high  $\phi$  composites) [54]. This swelling, like the stretching of linear DNA, promotes entanglements and threading by linear chains, which likewise facilitates thinning (Fig 2F). As such, we argue that rings switching between compacted and swollen states, underlies the phenomenon that the diffusion coefficient  $D$  is lower, and the zero-shear viscosity  $\eta_0$  and thinning exponent  $\gamma$  are higher, for linear versus 90-ring DNA composites at  $0 \leq \phi \leq 0.5$ , whereas rings become slower and exhibit enhanced bulk viscosity and thinning compared their linear counterparts beyond  $\phi=0.5$ .

These emergent regions of the phase space, indicate that composites can exhibit scale-dependent dynamics tuned by the relative concentrations of DNA and dextran as well as the DNA topology. These data also demonstrate the need for coupled microscale and bulk measurement methods to shed light on the physics underlying the rheology and transport properties that complex systems manifest. A final example to demonstrate this point is the apparent discrepancy between  $D$  measured via DDM and  $\tau_D$  measured via bulk rheology for  $\phi=1$  linear DNA. For entangled linear polymers,  $\tau_D \approx L_0^2/D$  where  $L_0 \approx (L/l_e)a$  is the primitive path length of the polymer [8]. For our linear DNA solution, we measure  $D \approx 9 \text{ nm}^2/\text{ms}$  via DDM, within a factor of two of the value measured previously with single-molecule tracking [88]. Using this value gives  $\tau_{D,micro} \approx 920 \text{ s}$ , which is substantially larger than  $\tau_{D,bulk} \approx 25 \text{ s}$  measured via bulk rheology. However, because our entanglement density of  $Z \approx L/l_e \approx 10$  (determined from  $G_N^0$ , see Figs S3 and 2D) is well below  $O(10^2)$ , we cannot ignore contour length fluctuations (CLF), i.e., fluctuations in the length of the primitive path, which reduce the disengagement time [8]. Specifically, CLF contributions are predicted to reduce  $\tau_D$  according to the relation  $\tau_D^{(CLF)} \approx \tau_D \left(1 - \frac{X}{\sqrt{Z}}\right)^2$  where  $X$  is a numerical factor that is of order unity and predicted to be greater than  $\sim 1.5$  [8, 119]. Using  $\tau_D^{(CLF)} \approx \tau_{D,bulk} \approx 25 \text{ s}$  and  $\tau_D \approx \tau_{D,micro} \approx 920 \text{ s}$ , we compute  $X \approx 2.6$ , which is indeed of order unity and  $>1.5$ . Thus, not only do our bulk and molecular-level measurements align with one another, but, taken together, they demonstrate the significance of CLF contributions to entangled chain dynamics and shed light on the numerical factor that relates the two for entangled DNA.

## Conclusions

In summary, we have coupled bulk rheology measurements with fluorescence imaging and DDM analysis to directly correlate the bulk viscoelastic properties of entangled DNA-dextran composites to the corresponding microscale polymer transport (Fig 1). Importantly, we performed both measurements – at lengths scales that differ by  $\sim 4$  orders of magnitude – on the exact same samples, under the same conditions, and within minutes of each other. In this way, we explicitly connect macroscopic rheological properties to the underlying macromolecular dynamics (Fig 5).

We show that DNA-dextran composites exhibit topology-dependent non-monotonic dependences of both bulk rheological properties and macromolecular transport properties on the fraction of DNA comprising the composites. We attribute this emergent behavior to the different ways in which dextran polymers alter the conformation and self-association of ring and linear DNA via depletion interactions. Rings may be either compacted (at  $\phi \leq 0.5$ ) or swollen (at  $\phi = 0.75$ ) by dextran. When swollen, threadings by neighboring ring and linear DNA give rise to near kinetic arrest. For linear DNA, depletion-driven stretching and bundling of the DNA may either reduce connectivity (at low  $\phi$ ) or give rise to overlapping extended bundles of DNA with properties akin to semiflexible polymers (at high  $\phi$ ).

It is intriguing that such stark DNA topology dependence across scales could be driven by dextran polymers with  $R_g \simeq 19$  nm, an order of magnitude smaller than  $R_g (\gtrsim 280$  nm),  $l_k (\gtrsim 100)$  nm and  $l_e (\gtrsim 300$  nm) for the ring and linear DNA, preventing individual dextran polymers to differentiate between the two possible topologies of a neighboring DNA strand. Instead, it is the collective action of dextran polymers seeking to maximize their available volume (and thus entropy) that leads to the topology-dependent phenomena we report. We can qualitatively understand this effect in the following way.

One mechanism that short dextran polymers can use to increase their available volume in solution is to interpenetrate the DNA random coils. This interpenetration causing rings, with no free ends, to swell from random coil configurations to more open ring conformations to reduce excluded volume within the coil [54]. Alternatively, dextran volume maximization can induce compaction of rings [75]. However, compaction is more energetically unfavorable for the DNA, as it forces repelling DNA segments to be in close vicinity. Only when the dextran concentration is high enough, does the entropic gain from dextran volume maximization outweigh the energetic cost to collapse the DNA. At even higher dextran concentrations, we may expect aggregation of compacted rings to further minimize dextran excluded volume, analogous to the formation of bundles of linear DNA. In the opposite limit, at lower dextran concentrations, and thus higher DNA concentrations, the threading of rings by linear DNA and other rings, facilitated by dextran-mediated swelling, is more probable, and would counteract the drive towards compaction.

Conversely, for linear DNA, that does have free ends, interpenetration of a random coil by dextran drives a DNA strand to entropically stretch into an elongated structure, rather than a swollen open ring, to minimize the volume excluded to the dextran. Bundling of elongated linear DNA, which would further minimize excluded volume, is energetically unfavorable and requires DNA strands

to come into close contact with one another, which is highly improbable at tracer DNA concentrations ( $\phi = 0$ ), but becomes possible as  $\phi$  increases. As such, the maximal elasticity at  $\phi = 0.75$  for linear DNA arises because the DNA concentration is high enough such that bundling can occur without destroying network connectivity.

More generally, our results demonstrate that for polymer composites, the whole is not always equal to the sum of its parts, rather mixing polymers with distinct structures, sizes and topologies can give rise to emergent dynamics that can either span from microscopic to macroscopic scales or display scale-dependence depending on the composite composition. We further show that polymer end-closure plays an important role in interactions between the different species comprising the composites, with ring polymers conferring uniquely suppressed dissipation and relaxation.

### Supplementary Materials

We provide the following figures in Supplementary Materials: Fig S1. Gel electrophoresis of linear and ring DNA solutions; Fig S2. Sample images of labeled DNA from time-series recorded before and after bulk rheology measurements; Fig S3. Nominal entanglement lengths computed from the plateau modulus for DNA in DNA-dextran composites; Fig S4. Sample DDM intermediate scattering functions for DNA-dextran composites; Fig S5. Variations in the intermediate scattering function across different regions of interest; Fig S6. van Hove distributions show non-Gaussianity indicative of heterogeneous transport at short timescales.
